Received 1 March 2000/Accepted 8 June 2000

Adeno-associated virus type 2 (AAV2) has proven to be a valuable vector for gene therapy. Characterization of the functional domains of the AAV capsid proteins can facilitate our understanding of viral tissue tropism, immunoreactivity, viral entry, and DNA packaging, all of which are important issues for generating improved vectors. To obtain a comprehensive genetic map of the AAV capsid gene, we have constructed 93 mutants at 59 different positions in the AAV capsid gene by site-directed mutagenesis. Several types of mutants were studied, including epitope tag or ligand insertion mutants, alanine scanning mutants, and epitope substitution mutunts. Analysis of these mutants revealed eight separate phenotypes. Infectious titers of the mutants revealed four classes. Class 1 mutants were viable, class 2 mutants were partially defective, class 3 mutants were temperature sensitive, and class 4 mutants were noninfectious. Further analysis revealed some of the defects in the class 2, 3, and 4 mutants. Among the class 4 mutants, a subset completely abolished capsid formation. These mutants were located predominantly, but not exclusively, in what are likely to be β -barrel structures in the capsid protein VP3. Two of these mutants were insertions at the N and C termini of VP3, suggesting that both ends of VP3 play a role that is important for capsid assembly or stability. Several class 2 and 3 mutants produced capsids that were unstable during purification of viral particles. One mutant, R432A, made only empty capsids, presumably due to a defect in packaging viral DNA. Additionally, five mutants were defective in heparan binding, a step that is believed to be essential for viral entry. These were distributed into two amino acid clusters in what is likely to be a cell surface loop in the capsid protein VP3. The first cluster spanned amino acids 509 to 522; the second was between amino acids 561 and 591. In addition to the beparan binding clusters, hemagglatinin epitope tag insertions identified several other regions that were on the surface of the capsid. These included insertions at amino acids 1, 34, 138, 266, 447, 591, and 664. Positions 1 and 138 were the N termini of VP1 and VP2, respectively; position 34 was exclusively in VP1; the remaining surface positions were located in putative loop regions of VP3. The remaining mutants, most of them partially defective, were presumably defective in steps of viral entry that were not tested in the preliminary screening, including intracellular trafficking, viral uncoating, or coreceptor binding. Finally, in vitro experiments showed that insertion of the serpin receptor ligand in the N-terminal regions of VP1 or VP2 can change the tropism of AAV. Our results provide information on AAV capsid functional domains and are useful for future design of AAV vectors for targeting of specific tissues.

Adeno-associated virus type 2 (AAV2) belongs to the human parowirus family, which requires a helper virus for productive replication (5, 7, 8). The nonenveloped capsid adopts an icosahoral structure with a dlameter of approximately 20 nm. Packaged within the capsid is a single-stranded DNA genome of 4.7 kb that contains two large open reading frames (ORFs), rep and cap (35). Three structural proteins, designated VP1, VP2, and VP3, are encoded in the rap ORF and made from the p40 promoter by use of alternative splicing and alternative start codons. The three proteins share the same ORF and end at the same stop codon. The C-terminal regions common to all three capsid proteins fold into a β -barrel structure that is present in several viruses (31).

Their molecular masses are 87, 73, and 62 kDa, and their relative abundances within the capsid are approximately 5, 5, and 90%, respectively (26). Recently, AAV has attracted a significant amount of interest as a vector for gene therapy (6, 26). It has a number of unique advantages that are potentially useful for gene therapy applications, including the ability to infect nondividing cells, a lack of pathogenicity, and the ability to establish long-term gene expression.

Early genetic studies on deletion mutants of AAV revealed that capsid proteins were required for accumulation of single-stranded DNA and production of infectious particles (19, 38). Mutations in the C-terminal region common to all three proteins also abolished virion formation and failed to accumulate single-stranded DNA (32). VP1 was thought to be important for virus infectivity or stability because mutations in the N-terminal region unique to VP1 produced DNA-containing particles with significantly reduced infectivity (19, 38). In vitro

assembly studies (33) and capsid initiation codon mutagenesis studies (25) suggested that both VP2 and VP3 were required for capsid formation and production of infectious particles, and either VP1 or VP2 was required for nuclear localization of VP3. Recently, Hoque et al. (19b) have shown that the VP2 N-terminal residues 29 to 34 are sufficient for nuclear translocation and suggested that the major function of VP2 is to translocate VP3 into the nucleus. A recent insertional mutation study on AAV capsid protein revealed that mutations in the capsid gene could affect AAV capsid assembly and infection (30). Since the crystal structure of AAV was still unavailable, the functional domains of the AAV capsid proteins were mostly predicted based on information derived from other related autonomous parvoviruses, canine parvovirus (CPV), feline panleukopenia virus, and B19, whose crystal structures were available (1, 2, 40, 41). Sequence comparison of AAV to these viruses revealed a few conserved functional domains (9, 10), but the exact functions of these domains were not clear.

While certain groups of cells cannot be transduced by AAV (22, 27), AAV can transduce a wide variety of tissues, including brain, muscle, liver, lung, vascular endothelial, and hematopoietic cells (12-14, 16, 21, 45, 48). Recently, Summerford and Samulski (37) reported that heparan sulfate proteoglycan is the primary cellular receptor for AAV, and their group further revealed that the binding site lies within VP3 (30). In addition, human fibroblast growth factor receptor 1 and $\alpha_i \beta_i$ integrin were identified as coreceptors for AAV (28, 36). Attempts to alter the AAV capsid also have been made in order to expand the tropism of AAV. Yang et al. (47) showed improved infec-tivity of hematopoietic progenitor cells by generating a chi-meric recombinant AAV (rAAV) having the single-chain an-tibody against human CD34 protein. Girod et al. (15) showed that insertion of the L14 epitope into the capsid coding region can expand the tropism of this virus to cells nonpermissive for AAV infection that bear the L14 receptor. However, in both cases the normal AAV tropism was not disrupted. Ideally, for the purpose of retargeting, the normal AAV receptor binding would need to be modified so that rAAV infects only targets bearing the receptors for the engineered epitope.

In this study, we used site-directed mutagenesis to mutate the capsid ORF. Initially, 48 slanine scanning mutations were made in which two to five charged amino acids in the AAV capsid ORF were mutated to alanine residues by site-directed mutagenesis. We reasoned that since the mutations were an average of 15 to 20 amino acids (aa) apart and spanned the whole capsid gene, some of them would inevitably fall in or near the functional domains of AAV capsid. In addition, over 40 substitution and insertion mutations were made in a search for regions that could tolerate insertions for the purpose of retargeting AAV vectors. By analyzing these mutants, we obtained a preliminary functional map of the AAV capsid protein. Our results identified critical regions within the capsid that were potentially responsible for receptor binding, DNA packaging, capsid formation, and infectivity. In addition, we identified sites that were suitable for epitope insertions that might be useful for targeted gene delivery..

MATERIALS AND METHODS

Cell culture, Low-passage-number (passages 27 to 38) HFK 293 cells (17) and HeLa cells were grown in Dulbecco's modified Engle's modium supplemented with 10% fetal calf serum, penkillin (100 U/ml), and streptomycin (100 U/ml) at 37°C and 5% CO₂. Bi3 cells were propagated as described elsewhere (34). Construction of AAV captil mattant plasmids. Plasmid piM45 (previously called piM29-45 [23]) was used as the template for all matant constructions. Munagenesis was achieved by using the Strategene site-directed matagenesis kit according to the supplier's manual. For each mutant, we designed two PCR primers which contained the sequence of alanine substitution or insertion plus a

unique endonuclease restriction site finnked by 15 to 20 homologous by on each side of the substitution or insertion. The restriction site was designed to facilitate side of the substitution or insertion. The restriction site was designed to incilitate subsequent DNA acquencing of the matants and for potential insertion of tags or foreign epitopes. The PCR products were digrated with endounciests Dps1 to eliminate the parental plasmid template and were propagated in *Escherichia coli* XL-Bine (Strangane). Miniprep DNAs were corracted from ampicilifu-resistant colonics and were screened by restriction endonuclesse digestion. Positive clones were sequenced in the capsid ORF region. The capsid ORF was then subclosed back into the pIM45 backbone with Small and Sph1 to eliminate background matanions. The same mutagenesis strategy was used for poptide substitution and insertion mutant constructions. insertion mutant constructions.

Production of rAAV particles. To produce rAAV with mutant capsid proteins, we transfected 293 cells with three plasmids: (i) pIM45, which supplied either wild-type (wt) or mutant capsid proteins (23); (ii) pXX6, which contained the adenovirus (Ad) helper genes (46); and (iii) pTRUF5, which contains the green fluorescent protein (efp) gene driven by the cytomegalovirus (CMV) promoter and flanked by the AAV terminal repeats (22). In some experiments, pTRUF5 was substituted with CBA-AT, a recombinant AAV plasmid that contains the human oil-antitypein (hAAT) gene under the control of the CMV-B-actin promoter. The plasmids were mixed at a 1:1:1 molar ratio. Plasmid DNAs used for transfection were purified by the QIAGEN Maxi-prep bit according to the

supplier's manual.

The transfections were carried out as follows. 293 cells were split 1:2 the day before the transfection so that they could reach 75% confluency the next day. Ten 15-cm-diameter plates were transfected at 37°C, using calcium phosphate as ten 15-cm-diameter places were transfected at 37°C. Forty-eight bours after transfection, cells were harvested by centrifugation at 1,140 × g for 10 min, the pellets were resuspended in 10 mi of systs buffer (0.15 M NaCl, 50 mM Tris-HCI [pH AS]), and viruses were released by freezing and thawing three times. The crude rAAV lysates were treated with Bouzonaso (pure gradix, Nycomod Pharma AV5) at a final concentration of 50 U/ml at 37°C for 30 min. The crude lysates were at a man concentration of 3 J00 Min at 37°C for 30 min, and the supernature was subjected to further purification by iodizanol step gradient and heparan sulfate affinity purification as previously described (51).

To determine whether any of the mutants were temperature sensitive, the transfections were done in six-well dishes as duplicates at 39.5 and 32°C. Viruses

were resuspended in 250 µl of lysis buffer. All crude rAAV preparations were stored at -80°C until their titers were determined.

stored at -87°C until their there were determined.

Get electrophoreris, lummunoblotting, and immension-precipitation. Crude or purified rAAV samples were analyzed on sodium dodeopl sulfate (SDS)-10% polyzorylamide gols. The samples were mixed with sample buffer and boiled at 100°C for 5 mln before loading. For immunoblotting, the proteins were transferred to a Nitro-bond membrane at 4°C, and the membrane was probed with monoclonal antibody (MAb) B1, directed against the capitid proteins (43). The capitid bands were visualized by permidese-coupled secondary antibodies using ECI. (enhanced chemituminescence detection) (Amembam) as suggested by the number.

For immunoprecipitation, beparan column-purified rAAV samples were disted in 10 volumes of NETN buffer (0.1 M NaCl, 1 mM EDTA, 20 mM Tris-HCl [pH 7.5], 0.5% Nonidel P-40] and incubated overnight at 4°C in the presence of a MAb to the hemaggluthin (HA) epitope conjugated to Sepharose beads (BAbCo). For a segative control, MAb AUI-conjugated beads (BAbCo) were seed. AUI is a commonly used epitope, DTYRYI. After incubation, the samples were contribuged for 5 min at 17,600 × g at 4°C. The beads were washed three times with 1 ml of NETN for 10 mln at room temperature and resuspended in contain leading buffer. After contribustion, the superpostate was precipitated. protein loading buffer. After centrifugation, the supernatant was precipitated with 15% trichloroacetic acid on see for 1 h and centrifuged for 3 min at 4°C, and the petite was reaspended in loading buffer. The samples then were boiled in sample buffer and analyzed by Western blotting with MAb 81 as described

Virus filters. The infectious titers of cAAV-containing wt and mutant capside Virus filters. The infectious titers of tAAV-containing wt and mutant capside were measured at two temperatures, 39.5 and 32°C, for the alamine scanning amments and at 37°C for all other mutants by using the fluorescent cell assay, which detects expression of the glo gene. This was done essentially as described previously by Zolotakhin et al. (31), Briefly, 293 cells were seeded in a 96-well dish the day before infection so that they would reach about 75% confluence the next day. Serial dilutions of wt and matant rAAV-GFP crude preparations were added to the cells in the presence of AdS at a multiplicity of infection (MOI) of 10.7 The cells and before them into the presence of AdS at a multiplicity of infection (MOI) of 10.7 The cells and blanch term incoherence at 20°C (25°C at 26°C) and 30°C (30°C). added to the cells in the presence of Add at a multiplicity of intection (MUI) at 10. The cells and viruses were incubated at 37°C (or 32° and 93°C) for 48 h, and the titers were determined by counting the number of green cells with the fluorescence microscope. For each mutent, the infections were done twice and the average was taken. For mutants that contained a packaged CliA-AT gene, infectivity was measured by the infections center assay on 293 cells as previously described (31) and by enzyme-linked immunosorbem assay (ELISA) measurements. ment of hAAT secreted into culture media from infected cells as described

eleashers (34).

To determine the rAAV physical particle ther, we used the A20 ELISA kit (American Research Bioproducts). The crude rAAV stocks were serially dibtted and incubated with the A20 kit plate. The readings that fell into the linear range were taken, and the titers were read off the standard eccording to the manufac-turer's instructions. The A20 antibody detects both full and empty particles (44). To determine the titer of rAAV physical particles that were full (i.e., contained

FIG. 1. Distribution of alanine scanning and HA epitope insertion mutants. Positions of the alanine scanning mutants (colored circles or squares) and the HA insertim mutants (flagged circles or squares) are shown on a diagram of the putative secondary structure of the AAV capsid protein adapted from a comparison of parvovirus capild sequences by Chapman and Rossmann (9). Some important amino add positions and mutant positions are illustrated by numbers with short lines. Heavy arrows represent putative § sheets, and helices represent putative a helices. The five putative loop regions are numbered I to V. The colors of the circles indicate the phenotypes of the mutants as shown below:

Class	Mutant(s)	Color	Primary phenotype	Defect
1	med., mid2, mid9, mid11, mid13, mid14, mid16, mid17, mid29, mid32, mid38, mid43, mid44, mid45	Red	Wild type

DNA), we used the quantizative competitive PCR (QC-PCR) assay as described previously (51). The crode rAAV stocks (100 µl) were digested first with DNase Ito climitate contaminating unpackaged DNA in 50 mM Tis-HC (pH 7-5)-10 mM MgCl₂ for 1 h at 37°C and then incubated with proteinase K (Bochringer) in 10 mM Tris HCl (pH 8:0)-10 mM EDTA-1% SDS for 1 h at 37°C. Virsi DNA was extracted twice in phenot-chloroform and once with chloroform and then precipitated by ethanol in the presence of glycogen (10%). The DNA was washed with ethanol, dried, and dissolved in 100 µl of H₂O, and 1 µl of the viral DNA was used for QC-PCR. Sertai dilutions of the internal standard plasmid DNA with a deletion of GFF were included in the reaction, and the PCR products were reparated by 2% agarose gel electrophoreds. The densities of the target and competitor bands in each tane were measured using ZERO-Dacan image analysis system sufference (version 1.0; Scanalytics) to determine the DNA concentration of the virus stock.

of the virus stock.

Haparan cahman blading assay. The ability of mutants to bind to beparan sulfate was tested essentially as previously described (51). Crude rAAV preparations containing wt or mutant capsids were first subjected to indicated gradient purification. The 40% Isyay was then collected and loaded onto a 1-mt prequilibrated heparan column at room temperature (immobilized on cross-linked 4% besided agarose; Sigma H-6508). The flowthrough fraction, wash (3 column volumes), and 1 M NaCl cleate were collected, and equivalent amounts of each sample were mixed with SDS sample buffer and electrophorused on SDS-poly-acrytamide gels. The yield of capsid proteins in each fraction was monitored with MAD B1 by Western blotting and ECL detection.

sampse were muce with SLIS sample router and electropisherized on SLIS-postacrytamide gels. The yield of capsid proteins in cach fraction was monitored with MAB B1 by Western blotting and ECL detection. EM. Electron microscopy (EM) was done in the ICBR EM lab of the Uniwerlity of Florida. Indiannol gradient and heparan column-purified wt or mutant GFP-rAAVs were desalted and concentrated by using a Centricon 10 filter (Amicon). About a 5-µl drop of the virus sample was spotted onto carbon-coated grids and left for 1 min at room temperature. Excess fluid was drawn off, and the sample was washed three times with phosphate-buffered saline; 5 µl of 1% uranyl accesse was added for 10 a, and the grid was dried at room temperature for 10 min before viewing unter EM.

RESULTS

Generation of AAV capsid mutations. We began our studies by using alanine scanning site-directed mutagenesis in the hope that some of the mutants would be temperature sensitive (11). The mutants were constructed in the noninfectious AAV plasmid, pIM45, which contains all of the AAV DNA sequence except the AAV terminal repeats. There are approximately 60 charged clusters in the AAV capsid gene. Some of the clusters are overlapping; in those cases, only one cluster was chosen. For the initial round of mutagenesis, 48 sites, named mut1 to mut48, were targeted. These were spaced approximately equally over the capsid gene, with 12 mutants exclusively in VP1, 5 in VP2, and the rest in VP3 (Fig. 1). With the exceptions noted below, in each cluster, all charged amino acids were converted to alanine. The mutations were created so that they also contained a restriction site at the site of mutation to

8638 WU ET AL. J. VIROL

facilitate confirmation of the mutant sequence and subsequent insertion of foreign epitopes (Table 1). In addition, after sequence comparison of AAV serotypes 1 to 6, several other positions were targeted. mut28 and mut35 were made at positions where extra amino acids were found in AAV4 by sequence comparison with AAV2. mut32 was made by replacing TTT with AAA since TTT was not conserved among other AAV serotypes at aa 454. Finally, in mut29 and mut31, only one Arg residue was changed to Ala, and in mut45 and mut48, only one Lys was changed to Ala. The positions of the alanine scanning mutants and the specific amino acid substitutions are summarized in Table 1 and Fig. 1.

Infectious titer assays reveal four general classes of mutents. To determine the effect of each mutation on viral infectivity, we used either wt pIM45 or a mutant pIM45 plasmid to complement the growth of pTRUFS, pTRUFS is a recombinant AAV plasmid that contains the gfp gene under the control of a CMV enhancer-promoter (22). The resulting recombinant TRUPS virus contained either wt or mutant capsid proteins and could be titered for infectivity by counting green fluores-cent cells in the presence of an Ad5 coinfection. We had shown previously that the fluorescent cell assay produced titers within two- to threefold of those obtained with a conventional infectious center assay (51). Initially, each mutant was grown and titered at either 39.5 or 32°C to determine if any of the mutants were temperature sensitive. The experiments were done twice, and there was no significant variation in titer. On the basis of those titers, the mutants could be grouped into four classes (Fig. 2; Table 1). Class 1 contained mutants that have an infectious titer similar to the wt titer (less than 1 log difference; for example, mul1 and mul2). Class 2 contained partially defective mutants with infectious titers 2 to 3 logs lower than the wt titer (for example, mut4 and mut5). Class 3 contained temperature-sensitive mutants; three of these (mut26, mut27, and mut33) were heat sensitive, and two (mut28 and mut35) were cold sensitive. Class 4 consisted of 12 noninfectious mutants, whose titers were more than 5 logs lower than the wt titer.

Noninfectious (class 4) mutants and temperature-sensitive (class 3) mutants were defective in packaging DNA or in forming stable virus particles. To determine the probable causes for the different defective mutants, we focused first on class 3 and 4 mutants. For convenience, we ignored the fact that the temperature-sensitive mutants had low infectivity when grown at the partially restrictive temperature of 37°C (data not shown), and viral preparations for all class 3 and 4 mutants were made at 37°C. To determine if these mutants were able to make capsids, we used the A20 ELISA. The A20 antibody recognizes only intact AAV particles (43) and is useful for determining the physical particle titer irrespective of whether the capsids contain DNA (18). Eight of sixteen mutants that were tested were negative by ELISA reading (Table 2), indicating that they were unable to make capsids or that the capsids were unstable even in crude lysate preparations. All of these were class 4 (noninfectious) mutants and were classified as class 4b (Table 1; Fig. 1).

QC-PCR assays also were performed on most of the class 3 and 4 mutants. The QC-PCR assay measures the titer of AAV particles that contain DNase-resistant rAAV genomes (Fig. 3). We have shown previously that it provides physical particle titers that are equivalent to those obtained by dot blot assay but has better sensitivity at low particle titers (51). As expected, mutants that were negative for the synthesis of AAV particles by A20 ELISA were also negative by QC-PCR assay (Table 2; Fig. 3). Most of the remaining mutants, which were positive for A20 particles, were also positive for packaged viral DNA in the QC-PCR assay (Fig. 3; Table 2). This group of

noninfectious mutants (mut22 and mut37) were called class 4a (Table 1; Fig. 1). Their defect was not in packaging but rather in the binding, internalization, or uncoating steps of the viral entry process. One A20-positive mutant (mut31) was an exception in that it was A20 positive but DNA negative by QC-PCR assay. This meant that mut31 formed intact virus particles that were empty. To confirm this, mut31 was examined by EM (Fig. 4), and it did indeed make empty particles. In contrast, the partially defective class 2 mutant, mut4, produced particles similar to wr particles. mut31 was assigned to class 4c (Fig. 1; Table 1).

Some mutants are defective for binding the viral receptor. One potential cause for the reduced infectivity of class 2, 3, or 4 mutants might be that they were unable to bind the viral cell surface receptor, the first step of the infectious cycle. Heparan sulfate proteoglycan has been identified as the primary cell surface receptor for AAV (37). To test whether these mutants could bind heparan, we developed a heparan column binding assay (Materials and Methods). Iodizanol-putified wt or mutant rAAVs were passed through a heparan agarose column, and the AAV capsid proteins in the starting material and the bound (cluate) and unbound (flowthrough and wash) fractions were monitored by Western blotting using MAb B1, which recognizes all three capsid proteins (Fig. 5; Table 3). As expected, wt AAV had a high affinity for the heparan column, since little capsid protein was detected in the flowthrough and wash fractions, and most of the capsid protein was detected in the cluate. The same was true of most of the mutants tested (Fig. 5; Table 3). Two mutants, however, mut35 and mut41, bound poorly to heparan (Fig. 5). A third mutant, mu40, which is located about 20 as away from mu41, also bound with reduced affinity (Fig. 5). This suggested that the primary defect in these mutants was their inability to bind to heparan sulfate proteoglycan. We classified mut35 as class 3b (temperature sensitive and heparan binding negative), mut41 as class 2c (partially defective and heparan binding negative), and mur40 as class 4d (noninfectious and heparan binding negative) (Fig. 1; and Table 1).

Three class 4b mutants, mut20, mut25, and mut46, could not be detected by Western analysis (Table 3). This was consistent with the fact that they made no capsid that was detectable with the A20 antibody (Table 2). Additionally, mu27, a temperature-sensitive mutant, and two class 2 mutants, mut21 and mut39, did not give any Western signal with MAb B1 (Fig. 5; Table 3). The heat-sensitive mutant, mut27, was presumably unstable at the nonpermissive temperature used for growing this virus, mut21 and mut39 were partially defective when assayed in crude extracts (Fig. 2). The fact that they could not be detected by capsid antibody after iodixanol centrifugation suggests that these capsids were also unstable during purification. These mutants were assigned to class 2b on the basis of their capsid instability (Table 1; Fig. 1). The rest of the mutants in class 2 that bind to heparan were classified as class 2a, partially defective, and heparan binding positive (Tables 1 and 3; Fig. 1). The nature of their defect was not clear but presumably was due to some step in the infectious process that occurs after viral attachment to the cell surface.

Regions tolerating alanine substitutions do not tolerate other kinds of substitutions. We wanted to determine whether the class 1 mutants defined positions in the capsid genes that were truly nonessential for capsid function. To test this, we constructed a series of mutants in which either the sorpin receptor ligand, FVFLI (50), or the FLAG antibody epitope, DY KDDDDKYK, was substituted for capsid sequences at many of the class 1 mutant positions (Table 4). A number of class 2 and class 4 mutants were tried as well. The serpin substitution

"Superscripts 1 to 4 indicate that a restriction site was introduced as a result of the alarma substitution mutation: 1, Nhel; 2, Eagl; 3, Hpal; 4, Mbal.

(5 aa) was the same size as the largest alanine substitutions. The FLAG epitope is highly charged, as were many of the substituted wt sequences. As expected, substitutions at class 2 (partially defective) or class 4 (nonviable) positions did not produce infectious virus (Table 4). Surprisingly, although many of the class 1 serpin or FLAG substitutions produced some physical particles detectable with the A20 antibody, only one of the substitutions, serpin at an 34 (the mud3 position), produced infectious virus particles in substantial yield (Table 4). Most

infectious titers were reduced by 5 logs or more, and particle titers (as judged by A20 ELISA) were reduced or undetectable as well. Thus, although modification of charged residues in class 1 mutants to alanine was permissible, these regions of the capsid were nevertheless essential for capsid formation and were sensitive to other kinds of substitutions.

Putative loop regions and the N-terminal regions of VP1 and VP2 are able to accept insertions of foreign epitopes. We also chose several other sites for insertion of foreign sequences. For

FIG. 2. Infectious titlers of virus stocks containing wt and mutant capeld proteins. The GFP fluorescent cell assay was used to titar virus stocks of wt and mutant vitus stocks containing the pTRUPS genome. 293 cells were transfected with wt or mutest pIM45 complementing plasmid in the presence of pTRUP5 and pXX6 at 39.5 and 32°C. Cells were collected 48 h posttransfection and then frozen and thawed three times. The crude lyane was used to infect 293 cells at 39.5 and 32°C with Ad5 (MOI = 10). The log value of the average infectious titer (infectious perficies/millikiter) that was obtained from two independent experiments is shown. There was a significant difference between experiments. The distribution of mutants unique to VP1, VP2, or VP3 is shown at the top. Asterisks indicate temperature-semitive mutants; noninfectious mutants are indicated by check marks.

Superscripts 1 to 4 indicate that a restriction size was introduced at a result of the attribute substitution mutant; Ala has, string of alumine residues inserted after the indicated amino acid, HA, AU, His, or Ser ins, insertion of the HA, AU, His, or Ser epitope immediately after the indicated amino acid of wrice; Ser or FLAG sub, substitution of the Ser or FLAG epitope for the wr AAV capsid sequence beginning immediately after the indicated AAV amino acid residue. Amino acid tags: HA, YPYDVPDYA; AU, DTYRYL; HIS, HHHHHHH; Ser, FVFLI; FLAG, DYKDDDDK

these mutants, we chose to insert the less charged HA epitope, YPVDVPDYA. The target positions for insertion were the N-terminal regions of the three capsid proteins, VP1, VP2, and VP3, the C terminus of the cap ORF and seven positions (mutants L1 to L7) that were believed to be in loop regions of the capsid protein based on an alignment of the AAV capsid sequence to that of CPV (9). Since these sites were suspected to be on the surface of the capsid, insertions at these sites might not affect capsid assembly or stability (Fig. 1). Mutations in the loop regions had been targeted successfully before by Girod et al. (15), who were able to insert the L14 ligand at aa

587 without significant loss in infectivity.

Insertions at the N termini of VP1 (VPN1) and VP3 (VPN3) and the C terminus of the cap ORF (VPC) were not well

tolerated (Table 5). To eliminate the possibility that the defect in these mutants was due to the HA tag, other tags such as AU, His, and Myc were also inserted at the N termini of VP1 and VP3 and the C terminus of cap, and they also were not tolerated at those positions (Table 1 and data not shown). Insertions at three of the putative loop regions were also not viable (Table 5, mutants L2, L4, and L5). Mutants L4 (aa 522) and L5 (aa 553) were interesting in that they produced a significant yield of physical particles that were not infectious.

However, HA insertions were well tolerated at aa 34 within the N-terminal region of VP1, at the N terminus of VP2, and within three of the putative loop regions, loop I (mutant L1), loop IV (mutants L3 and L6), and loop V (mutant L7) (Table 5; Fig. 1).

Some HA insertion positions are on the capsid surface. To determine whether the HA insertion mutants contained the HA sequence exposed on the surface of the capsid, we used batch immunoprecipitation with HA MAb-conjugated beads. In each case virus was purified by iodixanol density centrifugation and heparan column chromatography to remove any soluble capsid protein that might be present in crude viral preparations. As expected, insertion of the HA tag at the N terminus of VP2 (mutant VPN2) produced a slight increase in the molecular weight of VP2 and VP1 compared to we protein. pIM45 (Fig. 6A, B1 mAb). Western blotting with the HA MAb confirmed that the HA tag was present in both VP1 and VP2 (Fig. 6A, HA mAb). In the case of the VP1 mutant (HA insertion at as 34 in VP1), only VP1 had a higher molecular weight and only VPI contained the HA tag (Fig. 6A), as expected. When the viable insertions, VPN2 (HA insertion at the N terminus of VP2) and VPI (insertion at aa 34), were treated with HA MAb-conjugated beads, substantial amounts of both viruses were precipitated (Fig. 6B, HA mAb). This demonstrated that in both cases the HA epitope was on the surface of the virus particle and accessible to the antibody. Control wt virus particles (Fig. 6B, pIM45), were not precipitated with HA MAb to any significant extent. The amount of virus in the starting material was monitored by Western blotting with B1 or HA MAb.

The putative loop HA insertion mutants, L1 to L7, were also incubated with HA MAb-conjugated beads. Although the insertions in some of these mutants produced noninfectious vi-

FIG. 3. QC-PCR many of we and mutant virus stocks to determine the DNA-containing particle thers. Crude viruses were treated with DNaso to digest unpackaged DNA and then treated with proteinase K to refease the packaged DNA. The virul DNA was extracted with phoenol-chloroform, precipitated with ethanol, and dissolved in water. Equal amounts of viral DNA were incubated with (from left to right in each panel) 100 fg. 1 pg. 10 pg. 100 pg. 1 ag, or none of the pTRUFS plasmid DNA containing a deletion in the gfp gene and emplified by PCR. The PCR products were separated on 2% agarous gols and viewed by ethidium brondled staining. The arrangement of lanes in each panel is the same. Results for wt pIM45 viral DNA at three dilutions (1:1, 1:10, and 1:100) are also shown (top left three panels). Molecular markets were included in the left lane of the top left panel.

PIG. 4. EM analysis of we (A) and mutant (mus4 [B] and mus31 [C]) rAAVs. The viruses were purified by lochlanoi step gradient contribugation and hoperun enhann chromatography as described elsewhere (51), concentrated in a Centricum II), and negatively stained with 1% uranyl acetate. Bar = 40 nm. Although the indizant of step gradient might be expected to remove empty particles, these particles apparently accumulate at the 25 to 40% interface, and a significant fraction are recovered during this purification step.

rus, they all produced sufficient A20 antibody-positive virus particles to test for the presence of the HA tag on the surface of the capsid. When this was done, all of the L series insertions were shown to be in the immunoprecipitate (bound fraction) compared to the wt (pIM45) control (Fig. 7A). This demonstrated that each of these insertions at putative loop sites resulted in the HA epitope being on the surface of the capsid.

We also checked whether these loop insertions affected heparan binding of the mutant capsids. Interestingly, two loop

FIG. 5. Heparan blading properties of mutant viruses. Iodizanol gradientpartited virus stocks were loaded onto a haparan column. Equivalent volumes of the starting, 40% iodizanol material (T), flowthrough (F), wash (W), and eluzed (E) fractions were separated on SDS-10% caylamide gels and Western blotted with MAb Bl. In some cases, the flowthrough and wash fractions were pooled (FW) and loaded together.

insertion mutants, L4 and L6, were found to bind heparan columns with reduced affinity (Fig. 7B), which probably accounted for the lower infectivity of these mutants in the standard fluorescent cell assay. The L4 and L6 insertions were near the heparan-binding-negative mutants mut35, mut40,

and mut41 (Fig. 1). All five of these heparan-binding-negative mutants were located between as 509 and 591, suggesting that this region within the AAV capsid constitutes the heparan binding domain of the capsid protein.

Changing the tropism of AAV. To determine whether we could change the tropism of rAAV by inserting a novel receptor ligand into the capsid, we constructed two mutant plasmids that contained a serpin receptor ligand. In one case the serpin

FIG. 6. Immunoprecipitation analysis of VP1 and VPN2 HA insertion reu-tants to determine the accessibility of the HA epitope. (A) Weatern blot analysis of indinated gradient-purified viruses with either B1 (left) or HA (right) MAb. of nonlinear gradient and heparan column-purified viruses were precipitated with HA antibody coupled to agaress beads. The bound virus (Anti-HA mab lanes) was clusted with SIAS sample beafirs and detected by Western blotting using MAb Bl. For comparison, virus that had not been treated with HA MAb (Total sample) was also Western blotted with the Bl antibody.

FIG. 7. Properties of HA insertion matams. (A) Immunoprecipitation of HA loop insertion mutams to determine whether HA is exposed on the capsid surface. Indicated gradient and heparan column-purified viruses were incubated with HA MAb beads as described for Fig. 6. The antibody bound (B) and unbound (UB) fractions were exparated on SOS-10% grls and detected by Western blotting with MAb B1. As a negative control, AU MAb was used in the panel marked AU. The piM45 panel contained recombinant virus made with the wt helper plasmid. (B) Heparan binding properties of wt and HA loop insertion mutants. The virus samples were treated as described for Fig. 5. Virus in the starting material (T), flowthrough (F), wash (W), combined flowthrough and wash (FW), or cluate (E) was detected by Western blotting with MAb B1. pIM45 is virus with wt capsid.

ligand FVFLI (50) was substituted for the AAV capsid sequence immediately after as 34. In the second mutant an expanded serpin receptor ligand, KFNKPFVFLI (50), was inserted at the N terminus of VP2, as 138 (Table 1). The mutant capsid plasmids were then used to package CBA-AT, an rAAV genome that contained the hAAT gene under the control of a hybrid CMV-B-actin promoter. As seen with the HA insertion mutants described above, the serpin mutants produced rAAV viral titers that were slightly (sixfold) lower in infectivity when titered by the infectious center assay on 293 cells (data not shown). However, when equal amounts of wt or mutant virus (as determined on 293 cells) were infected into IB3 cells, both mutant viruses showed substantially higher infectivity than wt (Fig. 8). The VP2 sorpin insertion was 15-fuld more infectious, and the VP1 substitution mutant was approximately 62-fold more active. This suggested that IB3 cells, a lung epithelial cell line believed to express the serpin receptor, were a much better target for the serpin-tagged chimeric rAAVs than wt and that the tropism of the mutant rAAVs had been changed. Because both mutants retained the wt heparan binding region, we also infected IB3 cells in the presence of heparan sulfate to see if they continued to use heparan sulfate proteoglycan for viral

FIG. 8. Infection of 1B3 cells with wt and mutant viruses containing a FIG. 8. Infection of 183 cells with wt and mutant viruses containing a scrpin ligand insperium. Bi3 cells (1.5 × 10⁵ per 15-mm well) were infected with AdS for 60 min at an MOI of 10 and washed twice with medium. The cells then were infected for 60 min at an MOI of 400 with rAAV containing a genome that expressed the hAAT gene under the control of a CMV-β-actin hybrid promoter. Pollowing infection, the cells were washed with medium and inouteted at 37°C. At 72 h postinfection, medium samples were taken to determine the AAT concentration by ELISA. All experiments were done in triplicam, and the average for each experiment is shown. WT indicates that rAAV containing a wt AAV capsid (grown by complementation with pIM45) was used. VPI virus was grown by complementation with a mutant plasmid containing the scrpin ligand sequence (FVFIJ) substituted for the AAV capsid sequence after as 34 of the cap ORF. VP2 virus contained a scrpin insertion (KFNKPFVFIJ) at the N torminus of VP2, as 138 of the cap ORF. In the +HS samples, rAAV infection was done in the presence of soluble heparan sulface at a concentration of 2 mg/mi.

entry. When this was done, both wt and mutant infectivity dropped to barely detectable levels (Fig. 8). Taken together, these findings suggested that the serpin-tagged viruses continued to use heparan sulfate proteoglycan as the primary receptor and were using an alternative coreceptor, presumably the scrpin receptor.

DISCUSSION

In this study we describe the phenotypes of 93 AAV2 capsid mutants at 59 different positions within the capsid ORF. Several classes of mutants were analyzed, including epitope tag or peptide ligand insertion mutants, alanine scanning mutants, and epitope substitution mutants. From this, we could identify some eight separate phenotypes (Fig. 1; Table 1).

Noninfections mutants. The bulk of the mutants that were noninfectious either were unable to assemble capsids or the capsids were unstable. These mutants (class 4b) were located predominantly but not exclusively in what are likely to be β-strand structures in the capsid proteins (Fig. 1). Two of these mutants were insertions at the N- and C-terminal residues of VP3, suggesting that both ends of VP3 play a role that is important for capsid assembly or stability. We note that Ruffing et al. (32) have previously characterized deletions of the C terminus of the capsid ORF, and these deletions also were

One noninfectious mutant, mut31, produced viable capsids that were empty. This mutant, which consists of a single amino acid substitution (R432A), was apparently defective in packaging viral DNA and is located in putative loop IV (Fig. 1). It is not clear what the mechanism of viral DNA packaging is. Ruffing et al. (33) demonstrated that empty capsids could assemble in the absence of viral DNA. Some studies have suggested that packaging is an active process that requires interaction of Rep proteins with capsid proteins (42) or possibly is

coupled with DNA replication (49). Further studies with mut31 may be helpful in understanding the mechanism of packaging. Most of the remaining noninfectious mutants (Fig. 1, class 4a) were capable of assembling capsids and packaging DNA.

These are likely to be defective in some aspect of viral entry or uncoating and will require further study to uncover the mech-

anism of the defect.

Receptor binding mutants. Two of the noninfectious mutants, mut40 and L4, were apparently noninfectious because they were unable to bind to heparan sulfate (Fig. 1, class 4d). Heparan sulfate proteoglycan is believed to be the primary cell surface receptor for AAV (37). Three other mutants also were identified as defective for binding heparan sulfate, two partially defective mutants (Fig. 1, class 2c) and one temperature-sensitive mutant (class 3b). Together, the five mutants were distributed into two clusters in loop IV that were separated by 40 aa. The first cluster spanned aa 509 to 520 (mut35 and L4); the second was between as 561 and 591 (mut40, mut41, and L6). Mutants L4 and L6 consisted of HA epitope insertions into the two heparan binding clusters. These were found to be capable of being immunoprecipitated by HA MAb, confirming that these positions were on the surface of the capsid. We note also that Groud et al. (15) reported that insertion of the L14 epitope at an 587, the position of our heparan-negative mut41 mutant, was capable of targeting the virus to the L14 receptor, thus confirming that this region is on the surface of the capsid. A heparan-negative insertion mutant also was reported by Rabinowitz et al. (30) while this report was in preparation; it fell near the first cluster at aa 522. Taken together, analyses of these mutants suggest that the putative loop IV region contains two blocks of residues that are on the surface of the capsid and involved in heparan sulfate binding.

A heparan binding motif which consists of a negatively charged amino acid cluster of the type XBBBXXBX (where B is a basic amino acid and X is any amino acid) has been identified in several receptors and viruses (19a). Regions containing these clusters also appear to be sensitive to spacing changes. Although no heparan binding consensus motif of this kind was found in our heparan binding mutants, there were basic amino acids near these domains. mul35, an insertion at aa 509, was near basic amino acids K507 and H509. Interestingly, K507 is conserved in AAV1, -2, -3, -4, and -6 and in AAV5 is an R. H509 is present only in AAV2 and -3. AAV1, -2, and -3 are known to bind to heparan sulfate, while AAV4 and -5 do not. Additionally, L4, an insertion at an 520, was near basic amino acids H526 and K527, and L6, an insertion at an 591, was near R585 and R588, H526 and K527 are conserved except for AAV4 and -5, while R585 and R588 are unique to AAV2. For all of these mutants, the insertions could have disrupted local conformation that hindered normal heparan binding. For mut41, R-to-A substitutions at aa 585 and 588 might contribute directly to reduced heparan binding. Finally. mut40 did not affect either basic amino acids or spacing within the capsid

Capsid regions that are on the surface of the virus particle. In addition to the heparan binding clusters, several other regions were also present on the capsid surface. These include four of the five putative loop regions (mutants L1 to L7), the N terminus of VP2 (mutant VPN2), and a region within the N terminus of VP1 at amino acid 34 (mutant VP1). HA epitope insertions at these positions were all capable of being immunoprecipitated with anti-HA antibody (Fig. 6 and 7). We note that the L1 insertion mutant at aa 266 had the peculiar phenotype of being partially viable (Table 1) but was not detectable with the A20 MAb, an antibody that recognizes a conformational epitope that is present only in intact viral particles. A

FIG. 9. Ribbon diagrams of a dimer of the AAV VP3 model built based on structural alignments with the VP2 capsid protein of CPV. The view is down an inosahedral twofold axis. The strands of the β-barrel motif are colored blue, and the portion of VP3 is green indicates the heperan binding region. The rest of VP3 is depicted in red. The blue ball identifies the location of residues R432 mutated to an alamine in mut31. The gray balls identify the location of residues 266, 477, 591, and 664 (which had HA insertions in mutatus L1, L3, L6, and L7, respectively). The large triangle indicates an loosahedral asymmetric unit.

nearby capsid-forming mutant made by Girod et al. (15) at aa 261 was also negative for A20 antibody binding. This suggests that at least part of the epitope for the A20 MAb consists of amino acids between 261 and 266 and confirms that this region is on the surface of the intact particle.

Of the positions identified as being on the surface of the capsid, we found six that potentially are capable of accepting foreign epitope or ligand insertions for retargeting the viral capsid to alternative receptors. These are the N-terminal region of VP1 (near aa 34), the N terminus of VP2 (aa 138), the loop I region (aa 266), the loop IV region (near aa 447 and 591), and the loop V region (aa 664). All of these locations

were capable of tolerating an HA (or serpin) insertion and produced recombinant virus titers that were within 1 to 2 logs of the wt value. Furthermore, HA epitope insertions at these positions were capable of being immunoprecipitated with an ti-HA antibody (Fig. 6 and 7). Two of these positions, when tested with a serpin ligand insertion or substitution, produced virus that was much more infectious on IB3 cells than wt virus. Curiously, both serpin mutants were still inhibited by soluble heparan sulfate, suggesting that heparan sulfate proteoglycan was still the primary receptor for these mutants and that the serpin receptor was being used as an alternative coreceptor. It is conceivable that one or both of these capsid positions is

8646 WU ET AL.

J. VIROL

involved in binding to one or both of the proteins that normally act as coreceptors for wt virus, fibroblast growth factor (28), or integrin $\alpha_u \beta_s$ (36). This would explain their partial defect on 293 cells and the recovery of infectivity on IB3 cells. Further studies will be needed to test this possibility.

Mutants with unstable capsids and temperature-sensitive phenotypes. Three mutants, mut21, mut27, and mut39, were found to have capsids that were unstable when purified through an iodizanol gradient. Iodizanol is an iso-osmotic gradient purification method that appears to be gentler than CsCl centrifugation (51). Thus, these mutants appear to be particularly sensitive to capsid denaturation. mut21 and mut27 are in putative β sheets, and mut39 is in loop IV. It is worth noting that Rabinowitz et al. (30) also isolated an unstable capsid mutant at an 247 that is near the mut21 position, an 254. mut27 is also one of five temperature-sensitive mutants isolated during this study. The temperature-sensitive mutants and the unstable capsid mutants should prove useful in future studies for identifying steps in the capsid assembly or the infection process.

Viable and partially defective mutants. The two largest classes of mutants isolated were either wt (class 1) or partially defective (class 2a) with no identifiable defect (Fig. 1). Both class 1 and class 2a mutants were distributed either in the VP1 and VP2 unique regions or in the predicted loop regions of the capsid protein. We naively assumed that class 1 mutant positions, which produced viable capsids after substitution of two to five alanine residues, were regions that were nonessential for capsid assembly or stability and therefore should accommodate other kinds of substitutions. However, when serpin or FLAG epitopes were substituted at many of these sites, most of the mutants were nonviable, with the exception of as 34 in VP1. Indeed, many of these viruses were negative for capsid assembly and should also be useful for identifying possible intermediates in capsid assembly.

Ruffing et al. (33) showed previously that VP1 and VP2 but not VP3 contained nuclear localization signals (NLS), and three putative NLS are located in the VP1VP2 region at as 121 to 125, 141 to 145, and 167 to 171. Hoque et al. (19b) have shown that as 167 to 172 were sufficient to target VP2 to the nucleus, although their experiments did not rule out possible redundancy with the other two putative NLS sequences. All three of these putative signals were targeted with alanine scanning mutants (mut12, mut13, and mut15) in our study. Two of these mutants, mut12 and mut15, were partially defective, and the inactivation of an NLS may be the reason for their phenotype (19b, 33). We note that mut15 should have eliminated the NLS identified by Hoque and colleagues. The fact that mut15 was only partially defective suggests that there may be an alternative, redundant NLS sequences that are used by the capsid proteins. The third mutant (mut13) was classified as viable, but it also showed a lower than wt titer (Fig. 1).

Molecular computer graphics construction of an AAV model and structural localization of mutant residues. Because the AAV crystal structure is not available, the atomic coordinates of CPV VP2 (PDB accession no. 4DPV) were interactively mutated using the program O (20) to generate a homology-based model of the AAV capsid, using modifications of the alignments of the AAV major capsid protein (VP3) with the VP2 capsid protein of CPV (9, 15). The mutations were followed by refinement constrained with standard geometry in the O database. The model provided a means for preliminary structural identification of the heparan receptor attachment sites in the surface depression (dimple) near the twofold icosahedral axes of the capsid, surface loop regions which can tolerate foreign peptide sequence insertions, and a possible explanation for the phenotype of mut31 (Fig. 9).

The topographic location of the putative heparan binding region is consistent with regions that have been suggested as being involved in host cellular factor(s) recognition and implicated in tissue tropism and in vivo pathogenicity for other parvoviruses (3, 4, 24, 39). It is of interest that the putative heparan binding site is adjacent to a region of the AAV capsid that contains a peptide insert when the AAV VP3 sequence is compared to that of CPV VP2 and the VP2 of most of the other autonomous parvovirus sequences (9). Also a similar insertion of peptide sequences compared to CPV (although not in a homologous region of the VP2 to that observed in AAV) is present in the capsid of Aleutian mink disease parvovirus and minute virus of mice, proximal to residues in the dimple depression which are implicated in tissue tropism (24). Thus, these insertions may be capsid surface adaptations that enable the capsids to recognize different receptors during infection. In the case of AAV, its dimple peptide insertion, which is absent in the other parvoviruses, may enable it to recognize heparan sulfate, which has not been implicated in cellular infectivity by any other parvovirus.

The model also clearly shows that regions of the capsid which tolerated the insertions of the HA epitope (i.e., at residues 266, 447, 591, and 664) are on the surface loops present between the β strands of the β -barrel motif (Fig. 9). The β -barrel motif forms the core contiguous shell of parvovirus capsids, while the surface loops make up the surface decorations, dictating the strain-specific biological properties of the members. The observation that these surface regions can tolerate foreign peptide insertion is an indication that they are not involved in the interactions that govern capsid assembly.

Finally, the model provides a possible explanation for the observation that mul31 (R432A) is able to form only empty particles. In the unassembled VP3 monomer, the side chain of R432, points toward the interior of the capsid and would most likely be in contact with DNA. If recognition and encapsidation of AAV DNA precede final capsid assembly and involve oligometric intermediates, then R432 contacts with DNA may be essential for initiating capsid assembly around a nascent DNA strand.

In summary, we have reported a preliminary analysis of mutants at 59 positions within the AAV2 capsid ORF. We have identified regions in the capsid proteins that affect infectivity, capsid formation, capsid stability, DNA packaging, and receptor binding. These mutants should be valuable for defining the functional domains of AAV capsid proteins and for dissecting the molecular mechanism of viral entry. Additionally, we have defined a number of regions in the capsid gene at which foreign ligands can be inserted and have demonstrated that insertion of a foreign receptor ligand at some of these positions can change the tropism of the virus. This is the first step in the development of the next generation of AAV vectors, which can be targeted to specific cellular receptors or tissues.

ACKNOWLEDGMENTS

We thank J. Kleinschmidt for kindly providing MAbs A20 and B1. We also thank R. J. Samulski for providing plasmid pXX6. We acknowledge the Vector Core Laboratory at the Powell Gene Therapy Center, University of Florida Medical School, for technical assistance on rAAV production. We thank Corrine Abernathy, Daniel Lackner, and Eric Kolbrener for help on this project.

BEST AVAILABLE IMAGES

Defective images within this document are accurate representations of the original documents submitted by the applicant.

Defects in the images include but are not limited to the	items checked:
☐ BLACK BORDERS	
☐ IMAGE CUT OFF AT TOP, BOTTOM OR SIDES	
☐ FADED TEXT OR DRAWING	
☐ BLURRED OR ILLEGIBLE TEXT OR DRAWING	
☐ SKEWED/SLANTED IMAGES	e jakan
☐ COLOR OR BLACK AND WHITE PHOTOGRAPHS	
GRAY SCALE DOCUMENTS	
☐ LINES OR MARKS ON ORIGINAL DOCUMENT	L'AMERO SERRE, EL
☐ REFERENCE(S) OR EXHIBIT(S) SUBMITTED ARE POO	R QUALITY
OTHER:	Compr.

As rescanning these documents will not correct the image ing in problems checked, please do not report these problems to the left image.
